Abstract

In this preliminary work, we present an approach for augmentation of clustering with Natural Language Explanations. In clustering there are 2 main challenges: a) choice of a proper, reasonable number of clusters and b) cluster analysis and profiling. There is a plethora of technics for a) but not so much for b), which is in the general a laborious task of explaining obtained clusters. In this work we propose a method that aids experts in cluster analysis by providing iterative, human-in-the-loop methodology of generating cluster explanations. In a convincing example, we show how the process of clustering on a set of *objective variables* could be facilitated with textual *metadata*. In our case images of products from online fashion store are used for clustering. Then product descriptions are used for profiling clusters.

Keywords

XAI, clustering, metadata, Natural Language Processing, explanations, narratives

1. Introduction

Assigning labels to groups of similar objects is one of the ways how humans describe the world. It begins with a notion that some phenomena or entities differ from each other and that they could be divided into distinct classes. The clarification of the differences between groups gets better and better along with the knowledge gained about the instances that form different groups. Finally, one is giving names to those different categories of entities. In essence, clustering in machine learning is a no different process.

Clustering is an intrinsically subjective task and requires human assessment [1]. It is a purely statistical method which finds homogeneous groups of entities. It belongs to the family of the unsupervised algorithm in contrast to classification or regression, which are supervised. At every step of this process, the user makes decisions based on her/his domain

knowledge. Firstly, she/he needs to select features (variables) used by the algorithm. Secondly, the user selects the type of algorithm, similarity measures, number of clusters or size of the smallest one. Finally, she or he checks clusters by describing objects belonging to subsequent groups. It also follows that the process is iterative.

From our expertise in Industry 4.0 and e-commerce, we often see distinctions between 2 types of data. There are *objective data* and the *subjective data* or *metadata*. For instance in e-commerce popular approach for recommendations is Collaborative Filtering. It is based on finding users similar to each other in terms of interactions with products. Thus, *objective data* are shoppers' behaviors. Categories, titles, and descriptions of products are *metadata*, which are usually the result of the joint work of many e-store employees. For rolling steel factories, predictive maintenance models are derived mainly from *objective sensory data*, like temperature, force, etc. Factory accounting data are *metadata*.

The more *objective data* are, the more they are suited for modeling the phenomena, be it physical, business, sociological or psychological in nature. *Metadata* are more suited for explaining the model to the user, convincing her or him, and prompt to make decisions and actions based on this knowledge. They are more prone to error, because of their conventionality and subjectivism, but they speak to humans.

In this work we propose a method that allows for clustering dataset with *objective data*, and explain differences between clusters with *metadata*.

CEUR Workshop Proceedings (CEUR-WS.org)

We use XAI methods to explain differences between clusters using *metadata* which are perfectly understandable by humans, but may not be of enough quality to perform valid clustering. The selection of most interpretable *metadata* is iterative and human-guided. In our example we show how image-based clustering can be enhanced with textual description of clusters. We argue that such an approach can lead to better utilisation of *metadata* for cluster analysis purposes, which results in better understanding of clusters which is the final goal of every clustering task. Furthermore, it allows for checking the consistency between two or more possible instance representations (image and text) which might be crucial in domains that rely on both (e.g. e-commerce).

The rest of the paper is organised as follows. In Section 2 we present current research in the area of interactive clustering and human-guided cluster analysis. The description of our method along with use-case studies is given in Section 3. Finally, we conclude our work and show perspectives of its further development is presented in Section 4.

2. Related works

Explainable AI approaches have become particularly important, and although most work is generally focused on supervised learning, some works have been done to explain clusters. One of the most common methods for understanding clustering methods is visualization. By using low-dimensionality embedding and displaying them in two or three dimensions, one can get an overview of the clusters and their data. However, these visualizations are not always understandable and explainable.

The decision tree is one of the inherently interpretable algorithms. So one common way to explain models is to use decision trees. Nevertheless, the critical point for explaining the decision tree is its depth because decision trees with high depth no longer are interpreted, so we must pay attention to the depth of the tree produced. Using a small decision tree to divide a dataset into k clusters provides explainable clusters, but this approach has a trade-off between being explainable and accuracy. IMM algorithm [2] approximates k -means and k -median clustering by a threshold tree with k leaves. While ExKMC [3] uses a threshold tree to provide an explainable k -mean clustering in which the number of tree leaves is more than the number of clusters.

Besides, visualization or providing some conditions on features, using text data is reasonable to generate explanations to users. In [4] authors use

captions of the images along with images to create a more discriminative classification. In addition, they use this *metadata* to provide language explanation and generate a text description for each class. However, by blending textual and image modalities into one dataset, authors limits the possibility of checking consistency between these two types of data, and implicitly assume the correctness of possibly wrong image descriptions.

Similarly in many other methods that aim at explaining differences between discovered clusters, the clustering task is transformed to classification one, and the classifier is then explained with available XAI methods such as LIME [5], Anchor [6], LUX [7], etc. One of the most recent implementations of such approach can be found in [8].

Another approach is given in [9], where authors present a toolkit for conformance checking between expert knowledge with automatic clustering. The differences between expert-based clustering and automated clustering are justified with XAI methods and the process is iterative. However, the explanations are not human-guided, and the expert has no impact on the way they are generated. In particular, it is not possible to provide additional *metadata* for explanations, nor modify the set of concepts that are used for explanations.

In all of the cases the process is not iterative, nor human-guided. Finally, to the best of authors knowledge, neither of the approaches known in literature divide data into *objective* part with a good quality for cluster algorithms, but poor explanation capabilities and *meta-data* with possibly worse potential as clustering features, but better explanation capabilities and possible inconsistencies with *objective* data that should be fixed. Addressing these issues was the primary motivation of our work that will be described in more details in the following sections.

3. Cluster analysis with *metadata*

In this section, we will show how our method could be applied to real case scenarios. We choose an example from the e-commerce field because the authors have experience working in this industry. Specifically, we work with online stores to provide them, among others, with recommendations of products to their end-users (clients).

In real-life scenarios, data about products are stored in product catalogs in shop databases, and most often exchanged with so-called product feeds (XML documents). We used a public dataset from Kaggle¹. This dataset in terms of content resembles

¹See: <https://www.kaggle.com/datasets/paramaggarwal/>

a product feed for an online store of a medium size product catalog. It consisted of 44000 products with category labels, titles, and images. For the code accompanying this example see GitHub repository².

As been said before, we treat images as *objective data*. We used embeddings of images obtained via MobileNetV2 [10]. The fully-connected layer at the top of the network was disregarded because we were not interested in the classification done by the model. The output of the final layer of the model was of length 20480. We used Singular Value Decomposition (SVD) with normalization to reduce the dimensionality of embeddings, leaving at least 90 percent of the variance.

In this section, we will present tools dedicated to data scientists who would like to perform clustering. We propose a 2-step clustering loop, which consists of k-means clustering and textual explanations of clusters. Data preparation also could be performed more than once, if needed. For the sake of simplicity, we call it "step 0" in this work.

3.1. Data preparation

The method requires 2 types of data: *objective* and *metadata* as defined in the previous section. In "step 0" method provides users with helper functions to prepare both types of data. For *objective data* there is a function that performs a reduction of dimensionality via SVD followed by normalization. It works on any numerical data, which could be as well as one-hot variables and continuous real values (floats). User sets percent of explained variance left after SVD reduction. The optimal count of new dimensions could be determined automatically by our algorithm. This is done by probing different dimension counts with `scipy.optimize` package, so the user does not need to do this manually. As for *metadata* which are textual, there are wrappers built on top of `SpaCy`³ and `NLTK`⁴ libraries. Users can contact text columns, lemmatize, remove stopwords and perform Tf-Idf vectorization. For numerical *metadata*, we found a way to incorporate them into textual explanations. For instance, the year could be recoded as the label "year2022", which will be easily interpreted along the pipeline. Other numerical variables could be recoded to low/medium/high bins, based on quartiles. Finally, the user constructs the "Pipeline" object and initializes it

with 2 datasets: *objective* and *metadata*.

3.2. Assistance in clustering

The first step corresponds to running the unsupervised algorithm. Typically, the person who performs the analysis starts with the dilemma of choice of the number of clusters. It can be resolved with her/his background knowledge, intuition, practicality prerequisites, or just a trial and error approach. To give our users a hint in this regard, we use the T-SNE [11] 2-dimensional projection of the data. At the moment, this is a solely visual clue. It is depicted on Figure 1. If data have an underlying

Figure 1: Preliminary visualisation of *objective data* in 2-D projection with T-SNE dimensionality reduction. Colors denote clusters discovered with a usage of *objective data*.

structure, points representing observations will cluster, which would be observed on the chart. As T-SNE on massive data could be resource intensive, the default is to run this process on random subsample and cache results. Additionally, users can apply textual labels to the T-SNE chart, plotted on a subsample of data, to avoid cluttering the chart. Labels could represent the most important pieces of *metadata*, like the label, observation id, and summary of description. The next clue is derived from the silhouette score on a plot in the Figure 2. The range of the number of clusters to be tested is provided in accordance with the previous clue. To speed-up computations, this plot could be obtained on a random subset, and results are cached for further reference. For now, the user interprets the plot on her/his own. Finally, clustering with k-means is performed on all observations. Visualization with

3.3. Interactive explanations

Figure 4: Example images of products from the *objective* data that were assigned to the same cluster.

Figure 5: Word cloud for a category of products presented in Fig. 4 generated with *meta-data*.

The second step is to explain clusters, so the person who performs data analysis can assess the result. We would like to give users agency in refining explanations. Thus, we provide her or him with the possibility to influence explanations by extending stopwords with his own terms. On the other hand, we initialize the whitelist with keywords like "year2022", defined in "step 0". Then we use the Tf-Idf vectorizer, taking into account the aforementioned lists. Vectors are used for training decision tree classifiers. The size of the list of additional terms is under the control of a user. She or he can change it and interactively observe the changes in a Figure 6. Moreover, there are presented example observations on Figure 4, word clouds describing clusters on Figure 5 and LIME [5] explanation for one instance of *metadata* Figure 7.

The last stage is a plot of the word cloud of each cluster, using the same Tf-Idf vectorizer. Plots are accompanied by examples of observations if data scientists should define visualization function and

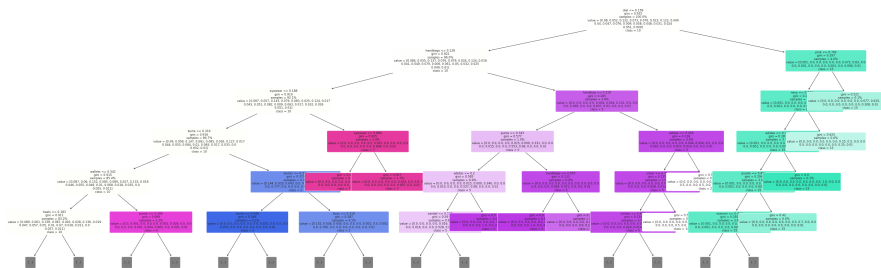

Figure 6: Decision tree classifier which explains how clusters differ in terms of *metadata*

pass into Pipeline class API. Moreover, there is random observation with the LIME explainer for a given class.

4. Summary

In this work we presented the method that allows for explaining clusters with concepts that could be more human-readable than data which was used as an input to clustering algorithm. We based our method on the observation that different types of data are suitable in different degrees to clustering and explaining tasks. We demonstrated the feasibility of our approach on the e-commerce example, where images were treated as input for clustering and textual descriptions of images as basis for cluster descriptions.

In future work we would like to improve our method with several extensions. We will focus on automatically proposing number of clusters based both on embedding features with techniques similar to T-SNE and metrics like silhouette score. We want to test other techniques clustering than k-means. For instance hierarchical clustering could be more suited in e-commerce, where taxonomies of products are multilayer. Word clouds could be replaced with topic analysis with Latent Dirichlet Allocation or techniques derived from Natural Language Generation. Another interesting direction is to construct explanations with other modalities, like visual, by something more sophisticated than presenting example images. It could be done for instance with image captioning.
